PRELIMINARY

Abstract

The regular provision of unconditional cash transfers to individuals is a tactic to fight poverty that has attracted significant interest from researchers and policymakers. Despite this interest, many fundamental questions about the effects of receiving sustained unconditional cash transfers remain. Open Research Lab, a nonprofit research organization, aims to help address this absence of data by conducting the U.S.’s first large-scale randomized trial of a guaranteed income. This document describes the design and analysis plan for the study. In the experiment, 1,000 participants will receive \$1,000 per month for 3 years. A control group of 2,000 individuals who receive \$50 per month will serve as the comparison group. The study offers an opportunity to inform both the debate over unconditional cash assistance and other questions about the effects of income that typically elude causal identification. This document focuses on the design of the study and intrahousehold outcomes.

1 Introduction

Since the late 1960s, income inequality in the United States has risen dramatically and the share of income going to the bottom half of the income distribution has fallen by over a third (Piketty, Saez and Zucman 2019). Intergenerational mobility has fallen, wage growth has stagnated for all but the most skilled, and the official poverty rate remains essentially unchanged despite decades of robust economic growth (Chetty and Hendren 2018*a*; Congressional Research Service 2019; U.S. Department of Health and Human Services 2016). Individuals and communities are struggling as opportunities are increasingly concentrated in urban areas and among the highly skilled. These trends have increased political and social divisions (e.g., Dorn et al. 2016), and the ability of existing social programs to stem them is limited.

Research shows that the current social safety net leaves many Americans cycling in and out of poverty and/or categorically ineligible for aid (Shaefer and Edin 2013; Danziger 2010; Ben-Shalom, Moffitt and Scholz 2012). The patchwork of programs is complex, costly to administer, and difficult to navigate. Take-up rates are often low, particularly among those most in need (Bhargava and Manoli 2015; Finkelstein and Notowidigdo 2019). Due to the high marginal tax rates and eligibility “cliffs” introduced at moderate income levels, families who do find work often face a difficult trade-off between earnings and the benefits they rely on for survival.

In response to these challenges, policymakers at state and local levels around the country have become increasingly interested in exploring unconditional cash transfers as a solution. Research points to negative economic, social, and psychological feedback loops that keep individuals with-

out a steady income “trapped” in poverty. Sustained unconditional cash transfers seek to break these feedback loops. Interest in unconditional cash assistance has recently skyrocketed, but the debate often relies on conjecture, stereotypes, and studies that are out-of-date, have important methodological shortcomings, or were conducted in very different contexts. This lack of data and experience impedes rigorous policy analyses and data-driven political debate.

To help guide academic, policy, and political debates, we plan to conduct an experiment that will provide new evidence about the effects of sustained unconditional cash transfers in the U.S. We are collaborating with two non-profit organizations that will implement a cash assistance program. Our partners will recruit approximately 3,000 individuals across two U.S. states and randomly assign 1,000 in total to receive \$1,000 per month for 3 years. We will conduct extensive quantitative measurement of outcomes related to individuals’ economic, social, and physiological self-sufficiency and well-being, as well as gather data on how individuals use their time and money and how their receipt of monthly cash transfers impacts their children and those in their households. We are partnering with state and local government agencies and private entities to measure many outcomes with administrative data. A single study cannot answer all questions about the effects of a guaranteed income, but we view this experiment as the strong foundation for a broader research agenda moving forward.

The experiment also offers the opportunity to speak to policy debates about unconditional cash assistance programs. Most directly, the study will provide evidence that will inform debates about the design of public benefits, including whether benefits should be provided as cash or in-kind, whether they should be provided monthly or annually, and whether transfer programs should be extended to groups that they do not traditionally target (such as young adults without children). More broadly, the study will allow us to better understand the relationship between income, work, and well-being generally, and it can provide new evidence on the mechanisms underlying rich-poor gaps in policy-relevant outcomes such as education, health, and time use. For example, unearned income may relax liquidity constraints and facilitate investments in health, human capital,

or geographic mobility that may provide long-run returns to households. Unearned income may also change individual bargaining power with employers, landlords, family members, romantic partners, and others. Additionally, unearned income may reduce the cognitive burdens that may be created by scarce resources (Mani et al. 2013), causing individuals to make different decisions. We discuss a broad array of additional channels through which unearned income may influence outcomes in subsequent sections.

2 Existing Research

Much of the existing literature on unconditional cash transfers in developed countries focuses on estimating effects on labor supply. Traditional economic theory predicts that unconditional cash transfers should cause individuals to work less (e.g., Becker 1965), while also consuming more of most goods. By providing nonwage income, cash transfers make household incomes less dependent on labor market earnings; this “income effect” allows households to consume more leisure. Based on this insight, much of the literature on unconditional cash transfers and welfare programs more broadly has focused on quantifying and understanding the determinants of income effects (Chan and Moffitt 2018).

Less work has been done measuring how unconditional cash transfers influence household consumption, which is the other impact of unconditional cash transfers predicted by traditional economic theory. Moreover, richer models suggest that unconditional transfers could have more nuanced effects than those predicted by traditional theory due to liquidity constraints, behavioral mechanisms, social interactions and spillovers, and other factors. More recent research has started to provide evidence on these broader effects of unconditional cash transfers.

2.1 Early experiments on unconditional cash transfers

To examine the effects of a negative income tax (NIT) on the labor supply of recipients, the U.S. government conducted four randomized experiments between 1968 and 1980, while the Canadian government sponsored one. A number of studies have aggregated the findings on reduced labor supply among participants across the four U.S. experiments, and these estimates range between a 5% and 7.9% reduction in the number of hours worked annually per individual for men; a 17% to 21.1% reduction for married women with children; and a 7% to 13.2% reduction for single women with children (Burtless 1986; Keeley 1981; Robins 1985).

The goal of the experiments was to examine the effect of a guaranteed income on labor supply, but supplemental analyses revealed positive effects on birth weight, homeownership, health, children's academic achievement, the number of adults pursuing continuing education, and other indicators of well-being (see, e.g., Hanushek et al. 1986; Widerquist et al. 2005; Murnane, Maynard and Ohls 1981; Weiss, Hall and Dong 1980; Rea 1977; Kehrer and Wolin 1979; Keeley 1980*b*; Baumol 1974; Maynard 1977; Elesh and Lefcowitz 1977; Maynard and Murnane 1979; Kaluzny 1979; O'Connor and Madden 1979). Similarly, a reexamination of Canada's guaranteed annual income experiment in the 1970s using health administration data shows a significant decrease in hospitalizations—particularly due to accident, injury, and mental health concerns—and an overall reduction in health service utilization among guaranteed income recipients relative to controls (Forget 2011; 2013). These overall improvements in health may lead to significant savings in health system expenditures.

Despite their path-breaking design, these experiments were plagued by nonrandom selection, errors in randomization protocols, differential attrition, nonparticipation, and systematic income misreporting, calling their results into question (Hausman and Wise 1979; Greenberg and Halsey 1983). Even without these empirical issues, the experiments were begun a half-century ago in a different economic and political context, so the results may not generalize to the present day. Moreover, the 1970s studies also did not track a number of outcomes that more recent research

suggests may play key mediating roles in the effects of unconditional cash transfers. The proposed study will employ research tools unavailable during the NIT experiments to generate a more holistic picture of the effects of the supplemental income on individuals. Tracking expenditures and financial data and leveraging a mobile application and web-based surveys to gather data on time use enable us to investigate how the cash transfers are spent and whether individuals are able to make investments that promote long-term economic self-sufficiency and build savings to help weather shocks and reduce vulnerability.

2.2 Evidence from the Earned Income Tax Credit (EITC)

The expansion of the Earned Income Tax Credit (EITC) in the early 1990s provided another opportunity to examine the effects of exogenous increases in income. Because it is linked to the amount earned, the EITC also affects beneficiaries' incentives to be employed and the number of hours worked, creating a substitution effect in addition to the income effect discussed above. Empirical research has suggested that the EITC increased labor force participation but had negligible impacts on hours worked (Eissa and Liebman 1996; Meyer and Rosenbaum 2001; Nichols and Rothstein 2016). Eissa and Hoynes (2004) show that while there is a positive increase in the labor supply of married men, the increase is more than offset by the reduction in labor force participation by married women, leading to an overall decrease in the total labor supply of married couples. There is ongoing debate about these estimates, however, as more recent analyses suggest that the observed effects on the extensive margin may be confounded by the simultaneous effects of welfare reform and a strong economy (Kleven 2018; 2020).

Additional research has investigated the effects of the EITC beyond measures of labor supply. By transferring money to lower-income households, the EITC substantially reduces the fraction of households in poverty. These gains are concentrated among families near the poverty level, however, and the EITC has little impact on those who are very poor (Meyer 2010). One analysis of maternal health before and after the expansion documented improvements in self-reported health

and mental health as well as reductions in the counts of risky biomarkers for cardiovascular diseases, metabolic disorders, and inflammation (Evans and Garthwaite 2014). Another EITC study found reductions in low infant birth weight that may be at least partially attributable to notable decreases in smoking during pregnancy and increases in prenatal care. More generally, the authors highlight that there are positive externalities to safety net programs that may lead policymakers to underestimate the benefits (Hoynes, Miller and Simon 2015). Other welfare reforms, such as Connecticut's Jobs First program, bundled multiple reforms together, making it difficult to determine the effects of individual components (Kline and Tartari 2016).

2.3 Natural Experiments

Unlike unconditional cash transfers, programs like the EITC affect beneficiaries' incentives to be employed and the number of hours worked because the amount of the benefit is linked to the amount of earned income. To address this limitation, several studies have examined the labor supply of lottery winners. Lottery studies generally find that the income effects of these transfers are modest. Using earnings data from the tax records of consenting Massachusetts lottery players, Imbens, Rubin and Sacerdote (2001) estimate that individuals with winnings up to \$100,000 reduce their earnings from labor by about 11 percent of the exogenous increase in income provided by their prize. The effect is larger for individuals between 55 and 65, and the marginal propensity to earn actually increases for those with the lowest pre-lottery earnings, although the effect is not statistically significant.

In a study of Swedish lottery winners, Cesarini et al. (2016) also find negative effects on labor supply, though much smaller in magnitude than earlier studies. The authors report that pretax earnings decrease by approximately 1.1 percent of the payout amount per year, mainly due to a reduction in wages from working fewer hours. It is also important to note that, for lottery winners with a large lump sum or large monthly payments, negative effects on labor supply could also be attributed to higher marginal tax rates on wages. Furthermore, the lottery studies generally

either had small samples (Imbens, Rubin and Sacerdote 2001) or took place in policy contexts very different from the U.S. (Cesarini et al. 2016).

Other recent quasi-experimental evidence of responses to exogenous increases in income comes from examinations of the Alaska Permanent Fund and casino disbursements to Native American families in the U.S. The Alaska Permanent Fund provides an annual unconditional cash transfer to every resident of the state. In 2019, this transfer amounted to \$1,606. Feinberg and Kuehn's (2018) analysis using data from the American Community Survey shows a negative effect of dividend receipt on hours worked. In contrast, Jones and Marinescu (2018) employ synthetic controls using data from the Current Population Survey and find no effect on the extensive margin and a small positive effect on the intensive margin. Available data was insufficient to determine if the latter is a result of people shifting from full to part time work or more people entering the labor force part time. A study of the effects of casino disbursements to Native American families found that a \$4,000 annual increase in income per adult had no effect on parental labor force participation (Akee et al. 2010).

In addition to the effects on labor supply, some of the recent quasi-experimental papers have examined broader outcomes. Research on casino disbursements to Native American families finds that an average increase in annual household income of \$1,750 is associated with statistically significant reductions in obesity, hypertension, and diabetes (Wolfe et al. 2012). Casino windfall cash disbursements have also been linked to higher achievement and educational attainment, reduced incidence of risk behaviors in adolescence, improvements in children's mental health, and better parent-child relationships (Akee et al. 2010; 2018; Costello et al. 2003). The Swedish lottery study found that winners consumed fewer mental health medications after winning, particularly those targeting anxiety (Cesarini et al. 2016). Though they did not report statistically significant changes in health service utilization and other indicators of health, the generalizability of the results to the U.S. context is questionable given the presence of universal health coverage and a generous social safety net.

2.4 Unconditional Cash Transfers in Developing Countries

There is also an important literature on cash transfers in a developing country context. Most of this work focuses on conditional cash transfers and children's outcomes (reviewed, for example, in Fiszbein et al. 2009). However, some studies leverage unconditional cash transfers and consider employment outcomes. Banerjee et al. (2017) review seven government-run cash transfer programs, plus Haushofer and Shapiro's evaluation of a Give Directly program in Kenya (2016), and find no systematic effect on labor supply on either the intensive or extensive margin.

One of the largest and most widely available of these recent cash transfer programs was the 2011 policy enacted in Iran that distributes the equivalent of 28% of the median per capita household income to over 70 million individuals. Despite the size of these transfers, no impacts were found on labor force participation (Salehi-Isfahani and Mostafavi-Dehzooei 2018). Individuals under thirty worked slightly less, though the effect was not statistically significant, and there were very small positive effects on labor supply for some groups (e.g., women and men in industrial and service sectors). These results may not generalize to the U.S., given the significant contextual differences.¹

Other studies have focused on the impacts of cash transfers targeted at business owners or workers in particular industries (de Mel, McKenzie and Woodruff 2008; Blattman, Fiala and Martinez 2014; Fafchamps and Quinn 2017; McKenzie 2015). Schady and Rosero's (2007) analysis of data from an Ecuadorian unconditional cash transfer program reveals no impact on the labor supply of recipients. In a study of three-generation households in South Africa, Bertrand, Mullainathan, and Miller 2003 find a sharp decline in both the extensive and intensive margin in working-age individuals' labor supply when an older individual in the household receives a pension.

¹There is also a large literature on conditional cash transfers in developing countries we do not review here.

2.5 Recent Experiments

More recently, there have been a growing number of conditional and unconditional cash transfer pilots in high-income countries. In the U.S., there have been two recent experiments with conditional cash transfers (CCTs) in New York City and Memphis, Tennessee, but results were mixed. The transfers reduced poverty and led to modest improvements in other areas that varied across sites, but researchers did not observe expected gains in academic achievement, employment, and health (Miller et al. 2016; Riccio and Miller 2016). However, a disproportionate amount of the cash rewards went to more advantaged families; in households that earned more rewards, parents had higher education levels and were more likely to be employed and married. There are a number of possible explanations for the lack of impact, including challenges with implementation, the complexity of the incentives, the process of documenting participation, and the small amount of money relative to the cost of living.

Finland recently piloted a basic income scheme targeted to those experiencing long-term unemployment. Two thousand unemployed individuals were randomly selected to receive 560 euros per month unconditionally for two years in lieu of traditional unemployment benefits. Final results are due in 2020, but no significant impacts were found on labor market participation in preliminary analyses (Kangas et al. 2019). It is important to note, however, that the control group was asymmetrically affected by changes to the unemployment system implemented in the middle of the experiment that require unemployment benefit recipients to prove they are looking for a job in order to continue receiving financial assistance. Though survey response rates were low, survey data indicated that basic income recipients experienced less stress, fewer symptoms of depression, and better cognitive functioning than the control group. Positive effects were also found on financial well-being, trust, and confidence in their future possibilities (Kangas et al. 2020).

3 Sample Definition and Sampling Procedures

3.1 Population

3.1.1 Eligibility Criteria

We define the population of interest as all individuals with Social Security Numbers between the ages of 21 and 40, inclusive, whose self-reported total household income in the calendar year prior to enrollment did not exceed 300% of the federal poverty level (FPL). In addition, we will exclude individuals that receive Supplemental Security Income (SSI) or Social Security Disability Income (SSDI), live in public housing or have a Section 8 voucher (also called Housing Choice Voucher) or other housing subsidy, and live in households in which another member receives SSI. Receiving an income supplement could jeopardize individuals' eligibility for housing assistance and SSI, and getting back on these benefits is very difficult and may take years. Losing this assistance could cause permanent harm, so these individuals will be excluded from the study.

3.1.2 Geography

The study will be conducted in regions in two states. Within each state, we chose a mixture of urban counties with large city centers, urban counties with medium-sized city centers, suburban counties, and rural counties.² We selected 1-5 counties of each type in each state that are demographically representative of counties of that type in the region. Nationally, roughly 19% of households that meet the eligibility criteria for the cash assistance program live in rural areas, 35% live in suburban

²Counties are divided into rural, suburban, small urban, medium urban, and large urban based on the share of households living in rural census tracts, the population density, whether the county is the largest in its metropolitan or micropolitan area, and population. Rural counties are those that have at least 50% of the population living in rural census tracts or population densities of less than 100 per square mile. Suburban counties are those that are not rural counties, but are not the largest city in their metropolitan or micropolitan area and have populations of less than two million. Small urban counties are those non-rural counties that are the largest in their micropolitan area but have urban cores of smaller than 40,000 people. Medium urban counties are those that are the largest in their metropolitan area, but have population densities of less than 1000 per square mile and populations of less than one million. Large urban counties are those that are the largest in their metropolitan area and have populations of at least one million or densities of greater than 1000 per square mile.

areas, less than 1% live in small urban areas, 17% live in medium-sized urban areas, and 28% live in large urban areas. Small urban counties make up a small share of the overall eligible population (less than 1%), so we excluded them from the sample. We aimed to recruit a sample that roughly matched these population shares, but we oversampled large urban areas to reduce recruitment and survey costs. This approach resulted in a sample of program participants composed of 13% individuals living in rural counties, 18% living in suburban counties, 16% living in medium urban counties, and 53% living in large urban counties.

3.1.3 Demographic Characteristics

In addition to the geographically stratified sampling described above, we used stratified random sampling to ensure that low-income individuals are over-represented in the sample of program participants and the share of males and females is approximately proportionate to their shares of the eligible population (which is roughly 62% female). Table 1 reports basic summary statistics of both eligible mailer respondents and enrolled program participants and compares both groups to the population mean characteristics computed using the American Community Survey for eligible households living in study counties. We report estimates of the eligible population both unweighted and reweighted to reflect the FPL group and county type stratification variables that were used.

On most dimensions, the characteristics of the sample closely match the eligible population in study counties. Our sample is slightly poorer, less likely to be Hispanic, and more likely to be female than eligible households as a whole. The biggest differences between our sample and the full eligible population are that our sample is more likely to report having a college degree and to be a renter than the eligible population.

Table 1: Study Sample Characteristics Compared to Eligible Population

	Eligible Population Comparison (ACS)				Study Sample		
	Full US Population		Study Counties		Eligible Mailer Respondents		Enrolled Active Survey Group
	Unweighted	Reweight to Match Enrolled Sample FPL Distribution	Reweight to Match Enrolled Sample FPL and County	Reweight to Match Enrolled Sample FPL and County Type	Unweighted	Reweight to Match Enrolled Sample FPL and County Type Distribution	Unweighted
(1)	(2)	(3)	(3)	(4)	(5)	(6)

	919,395	904,792	904,792	35,086	14,708	14,708	3,000

Notes: This table compares the study sample to estimates of the characteristics of the study in the US as a whole. Eligible individuals are those ages 21-40 with household incomes of less than 300% of the federal poverty line. Columns (1) - (4) report estimates of the characteristics of eligible households using the American Community Survey (ACS) 2013-2017 pooled sample. Column (1) presents the unweighted means for eligible individuals, Column (2) reweights this sample to match the enrolled sample distribution of income groups as a share of the FPL (which was a stratification target when assigning individuals to the active survey group), Column (3) reweights the ACS sample to match both the income group distribution and the county-type distribution in the enrolled active survey group sample, and Column (4) presents estimates of characteristics of eligible individuals in study counties, reweighted to match the enrolled sample FPL group and county type distribution. Columns (5)-(7) report characteristics of the study sample. Columns (5) and (6) report characteristics of eligible respondents to the mailer and online advertisement recruitment methods. Column (5) is unweighted, while Column (6) is reweighted to match the enrolled sample FPL and county type distribution. Column (7) reports the unweighted mean of the ultimate enrolled active survey group (i.e. the 3000 individuals assigned to the active group who answered the baseline survey).

3.2 Sampling Frames

3.2.1 Address-based Sampling

The majority of the sample—approximately 87%—was recruited through mailers. We selected addresses in eligible Census tracts from Target Smart (targetsmart.com). This vendor appends commercial data on name, income, race, and other available information to addresses from a variety of state and commercial sources. We understand that the accuracy of these commercial data varies widely, but using the data for targeting significantly improved the efficiency and cost of recruitment in pilots of the mailing strategy. About 69% of mailers were targeted to individuals

who appear income and age eligible on the basis of these commercial data. We refer to these as the “targeted mailers”.

To ensure that we did not systematically exclude from the sample individuals who are income and age eligible but did not appear as eligible in the commercial data (for example, because they moved or lost a job recently, they have missing or incomplete information in the commercial data, or they do not appear in any of the commercial data), the remaining 31% of the mailers were sent to addresses that were chosen randomly without regard to information from the Target Smart data. We refer to these as the “untargeted mailers.” Where data on names was available, we randomly selected one name per household to whom to address the letter.³ We appended “or Current Resident” to the end of each name.

We sent mailers to Census tracts roughly in proportion to their share of the eligible population within the county type in the region. For example, if a Census tract contains 2% of the eligible households in rural counties in a state, that county was sent roughly the number of mailers required to ensure that the tract represents 2% of the ultimate sample. The number of mailers this procedure required for each tract depended on the share of households in the tract that are eligible for the program, the targeting effectiveness of the commercial data, and the share of respondents we aimed to recruit using targeted versus untargeted mailers. Ultimately, we sent mailers to 1,138,130 unique addresses, making up about 23% of households in the average Census tract in the study.⁴

To identify the optimal mailing strategy and generate variation in selection into the study, we randomized both the number of letters sent to each address (ranging from one to four) and the gift card incentive offered for completing the online screening questionnaire, which ranged from \$0 to \$20. Roughly 2% of mailed households received one letter, 55% received two letters, 26% received three letters, and 17% received four letters. In terms of gift cards amounts, 37% of households received no gift card, 21% received \$5, 17% received \$10, 2% received \$15, and 23%

³For the “targeted” mailers and 50% of the “untargeted” mailers, we randomly selected one name per household among those names that appear age eligible in the commercial mailer data.

⁴The exact share varies with response and eligibility rates across different geography types.

received \$20.

3.2.2 Alternative Recruitment Methods

In an effort to include in the sample participants selected differently from those who chose to respond to mailers, we employed two alternative methods to recruit the remaining 13% of the sample. First, the partner organizations purchased ads on the Facebook and Instagram platforms that were shown to all age eligible individuals located in program counties. Participants recruited through this method make up about 1 percent of study participants.

Second, the partners placed ads on the Fresh EBT platform. FreshEBT is a free mobile application developed by Propel (www.joinpropel.com) that allows Supplemental Nutrition Assistance Program (SNAP, also known as food stamps) recipients to check their balance and manage their benefits. FreshEBT has over 4 million users nationwide, including more than 180,000 active users in the program counties. The partner organization recruited app users in eligible zip codes by placing ads for the study within the app. Participants recruited through this method comprise roughly 12% of study participants.

3.2.3 Mitigating Spillovers Between Participants

We took three primary measures to reduce potential spillovers between study participants (either through direct interactions or through changing housing or labor market conditions). First, we sent mailers in 6 waves, composed of 0.4%, 9.5%, 19%, 25%, 20%, and 26% of the total mailers, spread out over 8 months. We stratified the number of mailers sent across each wave within a Census tract. This meant that, at most, 6% of households in the average tract received a mailer during any given mailer wave.⁵

Second, we capped the number of households we randomized into the program participation

⁵There are a few rural counties where we needed to send mailers to essentially all households within the county during the course of recruitment.

group at 2 for each Census block and 20 for each Census tract. This reduces the probability that participants in the program interact socially.

Third, prior to randomization into treatment and control, we conducted a survey of study participants to ask if they knew anyone else in the study and, if so, who that person was. Individuals who knew another person in the program were randomized in clusters with the other person(s) they knew in the study to avoid spillovers between people with different treatment status. For more details, see Section 4.5 below.

4 Recruitment and Randomization Procedures

4.1 Recruitment to Eligibility Survey

4.1.1 Mailers

The non-profit organizations implementing the cash assistance program first sent the mailers described above, informing individuals they may be eligible to participate in a new program in which participants receive “\$50 or more” per month for three years. Following Broockman, Kalla and Sekhon (2017), the mailers directed recipients to a website where they could register their interest in the program and complete a short eligibility screening survey. This screening survey collected demographic data that was used to verify eligibility for the program (e.g., household size and income to determine if respondents’ incomes were below the cap, age, participation in public assistance programs). Respondents were also presented with an e-consent form to give the research team permission to access their administrative data. In order to facilitate linkages to administrative data, individuals who consented to share admin data had the option of providing their social security numbers during this process. Consent to share admin data was not a requirement for program participation, and it did not affect the probability of being selected for the program or randomized into the treatment group.

The partner organizations provided a phone number on the letter that people could call with questions or to receive assistance accessing and completing the survey. Ultimately, 38,823 individuals responded to the mailers and completed the eligibility survey, of whom 12,745 were program eligible (33%).

4.1.2 Facebook and Instagram

As described above, each implementing partner organization purchased ads that appeared on Instagram and in the Facebook news feeds of users in all eligible counties who are predicted to be age-eligible for the program. The ads ran for 1-3 weeks and had varied levels of concentration, as measured by ad spending, by zip code group in each state; more money was spent on ads in zip code groups with the highest poverty rates.

The ad included a thumbnail picture of a calculator and a notepad with a list of monthly bills and text announcing a new program in which “Participants will receive \$50 or more per month.” Clicking a button that said “Learn more” directed respondents to a website hosted by each partner organization that included a brief description of the program, contact information for questions, and a link to complete the same online eligibility survey that mailer recipients completed.

4.1.3 FreshEBT

Also as described above, each implementing partner organization posted ads on the FreshEBT app to users in eligible counties. These notices ran for 1-2 weeks and advertised a “new financial assistance program” in which “selected participants receive \$50 or more per month.” When a user clicked the “Learn More” button, they were directed to a short form that collected their email address, phone number, age, and zip code. Age-eligible respondents who confirmed that they live in an eligible zip code were sent an email that provided instructions to complete the same online eligibility survey administered to individuals recruited through other methods.

4.2 Randomization 1: To In-Person Enrollment or Passive Monitoring

We then randomized individuals to be targeted for in-person enrollment or to remain in an “administrative data only” control group. Though individuals in the latter group will not participate in any research activities, their de-identified administrative data can be used for comparison on outcomes measured using these data.

Once we had a pool of eligible individuals, we blocked participants by demographics (age, gender, and race) and pre-treatment values of high-priority outcomes collected in the eligibility survey. We randomly assigned participants to the **“administrative data control”** or the **“program participation”** sample. To ensure that we met our demographic quotas⁶ in the program participation group, we sent a larger number of mailers than required to reach our sample size and then randomly selected the program participation group to satisfy the demographic quotas. This means that participants had different probabilities of assignment to the “administrative data control.” We include all eligible screener respondents who are not randomized into the program participation group in the administrative data control group, but we will reweight the administrative data control group to have the same demographic averages as the program participation group.

In total, 9,504 individuals were placed in the “administrative data control” group, of whom 55% consented to share their non-health related administrative data, yielding an admin control group of 5,266.^{7 8}

We plan to compare outcomes measured using administrative data for the administrative data control group to the control group enrolled in the main study (as described in Randomization 2

⁶There are three demographic quotas that we targeted for the sample. Specifically, we designed the randomization to ensure that i) the share of women in the sample resembles the share of women in the eligible population in study counties; ii) the sample is least 20% non-Hispanic White, 20% Black, and 20% Hispanic; and iii) the household income of at least 30% of the sample is 0-100% of the federal poverty level (FPL), the household income of at least 30% is 101-200% of FPL, and the household income of no more than 25% of the sample is 201-300% of FPL.

⁷Individuals in the admin control group are disproportionately in the middle and high income groups (with household incomes of 101%-200% and 201%-300% of the FPL) given the need to assign households with incomes of 0-100% of the FPL to the program participation group with higher probability in order to achieve our sample income group target goals.

⁸A smaller proportion, 51%, agreed to also share health related administrative data.

below). This comparison will reveal whether participation in the study and receipt of the \$50 per month transfer had any effects on outcomes.⁹

4.3 In-Person Enrollment

The partner organizations then attempted to enroll individuals who had been randomized into the group targeted for in-person enrollment into the cash assistance program. As part of this enrollment, we administered the baseline survey to program participants who consented to take part in the research. We contracted with the University of Michigan Survey Research Center (SRC), a survey research firm with extensive experience fielding national studies, to manage recruitment and conduct in-person enrollment and baseline surveys. SRC employees aimed to ultimately complete 3,000 enrollments from the larger pool of possible participants. During the first 3 weeks of an attempted enrollment, interviewers made a total of 12 phone calls to primary and secondary phone numbers and sent follow up emails and text messages. The non-profit partner reached out to the individual at least once during week 4 if no contact had been made, and a different interviewer attempted 3 additional phone calls in week 5. If there had been no response after 6 weeks, we put contact on hold for two months before making another call and sending another text. If there was still no response, interviewers continued to call and text at least once per month until 3,000 participants had been enrolled.¹⁰

The in-person enrollment proceeded as follows:

- SRC staff first explained the purpose of the cash assistance program and the program pro-

⁹When conducting any such estimation, our estimand will be the average treatment on treated effect (ATT), weighting to the sample actually targeted for enrollment in the program. We had originally planned to conduct pooled analyses that estimated treatment effects by pooling our main analysis with an analysis that compared this “administrative data control” group to the treatment group that received the cash assistance. However, due to many participants having either very low or very high probabilities of assignment to the administrative data control group and the lower than anticipated take-up rate of the study among those assigned to the group targeted for in-person enrollment (due in part to COVID-19, which required enrollment to be done over the phone rather than in person), we do not plan to pursue this estimator for our final analysis. Our power calculations indicated that it would only increase our statistical precision by approximately 2%.

¹⁰Depending on response rates after the two-month break, interviewers in some cases attempted to reach individuals by visiting their home up to three times. In-person outreach stopped in March 2020 due to the COVID-19 pandemic.

cedures. Everyone was informed that they will receive "\$50 or more" each month for three years and that the specific amount will be randomly assigned, but the fact that some participants will receive \$1000 each month was not disclosed. This reduces the likelihood that the control group will know they are in the control group, as that knowledge may change their behavior in ways that would bias the results (including differential take up or attrition and a negative reaction to learning one is receiving less than others). Additionally, we did not want the prospect of a large cash transfer to coerce anyone into participating in the study.

- Individuals who agreed to participate in the program were enrolled in accordance with the procedures established by the non-profit organizations implementing the program.
- SRC staff then explained the purpose of the research and the study procedures.
- The explanation included the incentive structure for participation in research activities: \$50 each for completing in-person baseline, midline, and endline surveys, \$15 for each mobile baseline survey, \$10 for each short monthly survey, and \$10 per month for completing short activities on a mobile app. These incentives are taxable (unlike the cash assistance gifts), so we will send participants a 1099 if the participation incentive payments exceed \$600 per calendar year, although we intend to keep incentives under the threshold.

During study enrollment, the enumerators:

- Obtained informed consent and contact information for friends and family that can help us locate the participant if we cannot reach them.
- Collected names and demographic information for other members of the household and a description of their relationship to the participant, to help document spillover effects.
- Helped the participant install the custom mobile app and showed participants how to use it, if the participant had a smartphone and consented to using a mobile app.

- Administered the first and most comprehensive baseline survey, including collecting biomarkers (height, weight, and blood pressure).
- Helped the participant set up direct deposit for the research incentive payments. If the participant already had a bank account, the interviewer logged in to a custom-built payments processing system and allowed the participants to verify their bank account information. If participants did not have a bank account, they were given the option of opening an account at Chime Bank, an online bank with no monthly fees, no minimum balance, and no overdraft fees. If they chose this option, they received a Visa debit card in the mail within 7 business days.

4.3.1 Changes to Enrollment in Response to COVID-19

Enrollment began in October 2019, and 1,317 individuals were enrolled and completed the in-person baseline survey by March 14, 2020. On March 15, 2020, the University of Michigan imposed restrictions prohibiting all in-person research activities in response to the COVID-19 pandemic. All outreach was suspended and no enrollments were conducted for approximately six weeks. During that time, we worked with SRC to make the necessary adjustments so that interviewers could enroll participants and administer the baseline survey over the phone. With the exception of biomarkers and the cognitive tasks, all other data could be collected over the phone. Enrollments resumed in late April and all remaining participants were enrolled remotely by October 6, 2020. Ultimately, 44% (1317) of enrolled individuals were enrolled via an in-person baseline survey and 56% (1683) were enrolled via phone.

4.4 “Long Baseline”

Enrollments took place over a 12 month period (the “long baseline”). During this time, random assignment to treatment had not yet taken place; all participants who had been enrolled were

receiving the control group cash assistance gift of \$50 per month. In the month after a participant was enrolled, we administered three additional waves of web-based baseline surveys, notifying participants by text and email. These “mobile baselines” allowed us to collect data on outcomes that were not included in the in-person baseline. We also began distributing short web-based surveys each month that took approximately 10 minutes to complete. The purposes of these surveys are 1) to gather additional pre-treatment data to increase the precision of the estimates, and 2) to identify individuals likely to attrit from the study under the \$50 condition.

The desire to identify participants likely to attrit is primarily driven by concerns over differential attrition. As previously noted, the 1970s NIT experiments were plagued by differential attrition. Differential attrition also seems likely *ex ante*; even though participants will continue receiving their \$50 (in the control group) or \$1,000 (in the treatment group) monthly payments regardless of whether they participate in all of the surveys, individuals receiving \$1,000 per month may nevertheless be significantly more responsive than those receiving only \$50. In case this differential attrition occurs, we hope we can identify a large subsample *ex post* that did not exhibit differential attrition, as defined by their *ex ante* responsiveness. For example, we might conclude: “We see differential attrition on average, but among those who answered at least 2 of the 3 pre-randomization baseline surveys, we do not.” We will not, however, exclude any participants from randomization or change the probability of assignment to the treatment group based on whether they continue responding to surveys during the “long baseline.”

4.5 Randomization 2: Treatment and Control Groups

After all 3,000 individuals had been enrolled, we randomly assigned them to the “**treatment**” (\$1,000 per month) and “**program control**” (remain at \$50 per month) groups.

We used blocked and clustered random assignment as follows:

1. *Clustering.* We first formed clusters of individuals based on information that a small num-

ber of study participants knew each other. We placed individuals who reported knowing each other into the same cluster, such that they would always receive the same treatment assignment.

2. *Selecting the Waitlist.* We next selected a stratified random sample of 300 individuals in each state to be placed in a waitlist group. Only individuals not in a cluster with other individuals were eligible for this waitlist group. Within this waitlist group in each state, we formed 10 blocks of 30 observations, blocking on a number of pre-treatment characteristics. We then placed the observations on the waitlist in order such that each 10 observations contained one randomly sampled observation from each of the 10 blocks.
3. *Blocking.* We next “collapsed” the data to the cluster level to conduct a cluster-level random assignment. (The vast majority of individuals are in a cluster of size one with no other observations, but around a dozen clusters were of size two or three.) We then formed blocks of clusters as follows. We first formed strata based on race/ethnicity, income group, and state; any clusters with more than one individual within them were placed in their own strata. Within these strata, we formed blocks of three based on several dozen pre-treatment covariates using the `blockTools` package in R. When the number of clusters in a strata did not evenly divide into three, there were either one or two leftover clusters in a strata after the first round of blocking. We then conducted a second round of blocking for these leftover clusters, again forming blocks based on a set of pre-treatment covariates using `blockTools`.
4. *Random Assignment: blocks.* Within each block of three, we selected one of three observations to be in the treatment group and placed the remaining two in the program control group. Given that the number of clusters did not evenly divide into three, within the final block we sampled from the vector $\{0, 0, 1\}$ without replacement to assign treatment within the final block.
5. *Random Assignment: waitlist.* After the first random assignment, we computed the number

of *individuals* (not clusters) in each state that had been placed in the treatment group. Because the clusters are not of equal size, the number of individuals placed in the treatment group during the first random assignment step varies by randomization. We then calculated how many remaining individuals N from the waitlist would need to be placed into the treatment group in order for 1/3 of each state to be in the treatment group. For example, our target was to place 501 participants in one state (1/3 of the 1503 enrolled) into the treatment group; if 401 participants had been randomly assigned to the treatment group in the first randomization, we would place 100 of the state's 300 observations on the waitlist into the treatment group.

Recall that the waitlist had already been placed in a random order within each state. To select the individuals on the waitlist that would be initially placed in the treatment group, we simply selected the top N individuals on the waitlist.

6. *Re-randomization.* After conducting a randomization, we conducted a series of balance checks across several dozen pre-treatment covariates. Each pre-treatment covariate was associated with a different p -value floor, with covariates we deemed to be more important assigned a higher floor. We rejected any randomization where the p -value on a t -test was below the p -value floor for any of the individual variables. We also conducted an F -test for the joint significance of all of the same set of pre-treatment variables by outcome area and rejected a randomization if the p -value on any of these F -tests was over 0.25.

Through simulation, we verified that this procedure resulted in all observations having an exactly 1/3 probability of being in the treatment group.

4.6 Intervention

After random assignment, participants in the treatment and control groups will be notified about the amount of the cash transfer they will receive each month and the schedule for disbursements.

The intervention in this study is an exogenous increase in income in the form of unconditional cash transfers. The transfers (\$50 monthly for the program control group and \$1,000 monthly for the program treatment group) will be delivered by the implementing non-profit organizations via direct deposit to the participants' bank accounts.¹¹ All participants will be notified monthly when the payment is deposited into their account.

Receipt of the treatment transfers and the nominal transfer for the control group is not conditional on participation in any of the research activities and individuals can use the money however they choose. Note that the transfers are provided as a gift from a non-profit organization and will not be subject to income tax.

4.6.1 Waitlist

We originally expected that some participants may not have wished to receive the \$1,000 per month transfer (e.g., because they did not feel comfortable taking money they did not “earn,” or because it affects their eligibility for other benefits). During the first three months of the program, if any individuals assigned to the treatment group refuse the \$1,000 per month transfer, we therefore originally planned to go to the next person on the randomized waitlist in their state and offer that person the transfer instead. In practice, though, we only enrolled one person from the waitlist, in order to replace one participant assigned to the treatment group who was removed from the program for violating program rules. We therefore ignore the waitlist in our estimation strategy and analyze the experiment using intent-to-treat, following the original random assignment (since the compliance rate with the treatment was 99.9%).

¹¹The implementing partner organizations work with participants who do not have a bank account and who decline to or are unable to open a Chime account to ensure that they are able to receive direct deposits via a reloadable debit card or payment transfer app.

4.7 Outcome Measurement

4.7.1 Monthly Surveys

We plan to use Qualtrics to conduct monthly web-based surveys. Participants will be notified by a text message and an e-mail containing a personalized link to the survey, and we will ask them to complete the questionnaire at their convenience within 2 weeks. We will send reminders to nonresponders, and \$10 will be deposited to participants' bank accounts immediately upon completion. We plan to keep the surveys very short to reduce fatigue.

Maintaining regular contact allows us to identify changes in employment, housing, education, and other variables for which a change will trigger an additional module asking about the reasons for the change and collecting new data on relevant measures (e.g., housing quality following a move, job satisfaction and earnings for new job, etc.). We will spread the modules to be administered less frequently across months to keep the length fairly consistent. Questions pertaining to variables with higher likelihood for measurement error or misreporting due to difficulty remembering will be asked more frequently.

If we see large differential attrition from these surveys, we may abandon them and focus on collecting data during the midline and endline surveys. However, we do see the monthly surveys as an important way to maintain contact with respondents, and response rates were very high (over 90%) throughout the pilots.

4.7.2 Midline Survey

The survey firm will administer an in-person midline survey 15-18 months after the treatment group begins receiving \$1000 per month.

4.7.3 Endline Survey

The survey firm will administer an in-person endline survey towards the end of year 3, several months before the cash transfers will end. Respondents in the treatment group may behave differently during the last few months of the program in anticipation of the payments ending, so we will conduct this survey a bit early, starting at 2.5 years into the program and ending at least 3 months before the transfers cease. We hope to conduct long-run follow ups in the future after the program has ended to observe whether effects persist.

4.7.4 Administrative Data

We will gather a variety of administrative data which is described in more detail below.

4.8 Mobile Phone Application

Participants have the option to download a mobile phone application created for the study. We will use this mobile app for both passive and active data collection for consenting participants. We will administer 2-4 short activities each month through the app; participants who choose not to or are unable to download the app will be able to complete these activities via a web interface. From the subset of participants who consent to share anonymized location data, we will passively collect GPS location and accelerometer data from the participants' phones that we can connect to other data sources to potentially improve the precision of our estimates.

5 Estimation

We measure each outcome at multiple time periods and observe outcomes across many different substantive areas. To reduce measurement error and the number of hypotheses we test, we pre-specified the following estimation procedure, drawing on Anderson (2008), Finkelstein et al. (2012), and Guess et al. (2023). Table 2 provides an overview.

5.1 Pooling items across time

Our primary hypotheses rely on effects of the treatment on versions of the items¹² that are pooled across time. In order to pool across time, we average individual outcomes across the study period, placing greater weight on later time periods.¹³ If we have no measures of an item within a particular time period (e.g., year 2, at midline, etc.) for an individual but do have measures of that item at other time periods, we will replace that item's outcome for that individual at that time period with the treatment-arm-specific mean, following e.g. Kling, Liebman and Katz (2007).

Because we observe higher response rates and less differential attrition in the midline and endline surveys than in the mobile monthly surveys, we perform this aggregation twice: (1) we compute one set of estimates using data only from the midline and endline surveys and (2) we compute another set of estimates also including data from the mobile surveys. The latter set of estimates places 70% of the weight on the midline and endline surveys and 30% of the weight on the mobile surveys when items are observed in both, although some items are only observed in the mobile surveys.

¹²In some cases, what we consider a single item might be a composite based on multiple survey questions. Any such combination of multiple survey questions into a single item would be pre-specified in the topic-specific section of this PAP below.

¹³For the midline and endline estimates, we place 70% of the weight on the endline and 30% of the weight on the midline. For the monthly surveys, we place 50% of the weight on surveys conducting in the final year, 30% of the weight on surveys conducted in the second year, and 20% of the weight on surveys conducted in the first year. When aggregating the monthly surveys by year, average within item within respondent across all non-missing responses for that year. We code each respondent's response to each item within each year as missing only that item is never observed for that respondent within that year.

We refer to these individual outcomes as *primary items* when we pre-specified that they represented primary outcomes. For example, one of the items is a dummy variable which is set to one if the individual has recorded over three moves within the past year. To estimate treatment effects on the individual items, we first average the item across time using the procedure described in the previous paragraph.

5.2 Item-level effects

The first step in our estimation is to estimate the effects on the individual items, either pooled across time or at individual times.

To estimate these estimates, following Bloniarz et al. (2016), we first predict the item (or item pooled across time) using the Lasso to select pre-treatment covariates that predict the item. Next, to estimate the treatment effects we use OLS, regressing the item on a treatment indicator and the Lasso-selected pre-treatment covariates (in order to increase precision), with clustered standard errors. This yields a treatment effect estimate for every individual item (both at each time and pooled across time).

5.3 Component-level effects

Drawing on Anderson (2008), to reduce the number of primary hypothesis tests we conduct, we group primary items into *components*. (Some items are labeled as secondary or tertiary and are not in any components.) Which items were assigned to which components was pre-specified. For instance, we categorized the dummy variable for whether participants moved over three times within the past year in the ‘Excessive Residential Mobility’ component.

To estimate the effects on each component, we use seemingly unrelated regression with clustered standard errors. This procedure allows the standard errors to reflect the correlation between the estimates in each of the constituent regressions.¹⁴

¹⁴This is similar to the ‘pooled OLS’ approach described in Finkelstein et al. (2012), although in simulations con-

In particular, at each time period and separately on pooled versions of the items when pooling across time periods, we first estimate a system of equations using all of the item-level regressions described in the previous subsection. We then estimate an average of the estimated treatment effect from each of these regressions, weighting the estimate on each item equally. When taking this average, we rescale each item's estimates and standard errors so that the estimates are in terms of standard deviations (by dividing the estimates and standard errors by the standard deviation in the control group for that item). The effect at the component level can therefore be interpreted as the average effect on standardized versions of the individual items within that component.

We separately estimate effects on components using only data from the midline/endpoint and when also including data from the mobile surveys. Note that because some items were not asked on the midline/endpoint, and others were not asked on the mobile surveys, the estimates from the midline/endpoint-only specification and the midline/endpoint and mobile survey specification will not be directly comparable, as the midline/endpoint-only specifications may contain different items.

5.4 Family-level effects

Components are also grouped into *families*. For example, we categorized the 'Excessive Residential Mobility' component within the 'Housing Hardship' family.

To estimate effects on individual families, we use seemingly unrelated regression to test the hypothesis that the average of all the component-specific treatment effects is zero. In particular, we place all the individual regressions for the specific items within all the components within the family into one seemingly unrelated regression system. We then estimate all the component-level estimates as described in the previous section, and finally take the average of these component-level estimates. The effect at the family level can therefore be interpreted as the average effect on the components.

Which items are placed into which components and which families are listed in the topic-

ducted when preparing our pre-analysis plan we found that it had better statistical power for our data structure.

Table 2: Item Hierarchy

Level of Aggregation	Example	Estimation Approach
Primary Items, Pooled Across Time	Dummy Variable for Over 3 Moves Within 1 Year	Average the item measured at midline, endline, and in years 1, 2, and 3, placing more weight on later years and on midline/endline. Estimate treatment effects with OLS with clustered standard errors, controlling for Lasso-selected pre-treatment covariates.
Components, Pooled Across Time	Excessive Residential Mobility	Average treatment effect estimates on standardized versions of constituent items using Seemingly Unrelated Regression (SUR).
Family, Pooled Across Time	Housing Hardship	Average the treatment effect estimates on constituent components using Seemingly Unrelated Regression (SUR), taking the regressions on the components as inputs and weighting all components equally.
Secondary Items	Number of Moves in Past Year	Average item measured at midline, endline, and in years 1, 2, and 3. Estimate treatment effects with OLS with clustered standard errors, controlling for Lasso-selected pre-treatment covariates.
Tertiary Items	Number of Moves in Past 5 Years	Average item measured at midline, endline, and in years 1, 2, and 3. Estimate treatment effects with OLS with clustered standard errors, controlling for Lasso-selected pre-treatment covariates.
Heterogenous Treatment Effects	Effect on Excessive Residential Mobility Component by pre-treatment poverty category	Separately estimate treatment effects among each subset.

specific portion of the pre-analysis plan below.

5.5 Heterogeneous Treatment Effects

Given the sample size and the many hypothesis tests we already plan to conduct, we are concerned about statistical power. Therefore we pre-register that all heterogeneous treatment effect estimates will be considered exploratory unless explicitly pre-specified otherwise. Pre-analysis plans for some outcome areas may specify hypothesis tests for heterogeneous treatment effects and note them as exploratory or non-exploratory.

We plan to explore heterogeneity in treatment effects more thoroughly in a separate paper. We will pursue at least three approaches.

First, one may imagine that individuals have different preferences and circumstances that would contribute to how they use the transfers and their subsequent outcomes. For example, one individual may prioritize paying off debts, while another may prioritize going back to school. In evaluations of the Chicago Resilient Communities Pilot (CRCP) program and the Cook County Promise Pilot (CCPP) program, respondents were asked at enrollment to identify their top needs and priorities.¹⁵ We did not ask these questions at baseline for this study, though we did ask participants their preferences over a limited set of variables.¹⁶ Bearing in mind that baseline rates of an outcome variable are often very predictive of treatment effects (Vivaldi 2020), and based on the theory that individuals may be more likely to put their efforts into improving areas in which they are relatively deprived, we will seek to construct an estimate of what areas individuals might have prioritized had they been asked the question by considering which outcomes in the CRCP/CCPP “needs and priorities” module they had particularly low levels of at baseline.¹⁷ We can then use these priorities to weight each individual’s outcomes, similar to our approach in CRCP/CCPP, and to conduct heterogeneity tests. It is plausible that there are some outcomes for which we do not observe statistically significant effects on the whole sample, but which are significant for a certain subgroup.

We can also apply the same approach to the CRCP and CCPP data, for those outcomes for which we have baseline measures, to gauge how well our predictions of what respondents might

¹⁵These needs and priorities that participants of CRCP and CCP were asked about included: saving money; getting a new car or repairing my current car; finding a new place to live; finding a new job or getting promoted to a better position; being able to pay my bills; buying things I need (such as more or better food, clothes, etc.); reducing stress or anxiety; getting health, dental, or mental health care; paying off debts; buying things for my children (including gifts, child care, and health care costs); finishing my education or getting more education or training; growing my family; improving my romantic relationships or finding a new partner; finding more ways to relax or have fun; helping my community (for example, church or neighborhood); and helping my family members.

¹⁶Including their preferences over finding another job, pursuing more education, starting a business, getting pregnant, and whether they plan to move.

¹⁷Though we note that it is also possible that a participant having low levels of a variable at baseline instead signals that they are not interested in improving it.

find most important align with respondents' own priorities. Since policymakers often have to determine how to target programs without knowing individuals' own preferences, this exercise could also be of independent interest in learning about how well different kinds of targeting might work.

To further explore heterogeneity and ability to target, we will use a data-driven machine learning approach in which each site's variables are used to predict the best targeting of the program for a certain outcome in the other sites, using the full set of variables available across all sites. The best targeting of the program will likely depend on the outcomes prioritized. At a minimum, we will consider minimizing negative effects on employment rates and income, increasing educational attainment, and improving health outcomes observed in administrative data.

Finally, we will leverage a partial pooling analysis, described further in a later subsection of this plan, to characterize treatment effects for different quantiles of the data, as in Meager (2019). For this analysis, we will particularly focus on the 10th, 25th, 50th, 75th and 90th quantiles of the data for the continuous outcome variables for which we elicited forecasts.

Again, these more detailed analyses will be performed separately and are not the focus of this pre-analysis plan.

5.6 Robustness Checks

We perform a number of robustness checks to help assess the importance of several empirical concerns.

To assess the impact of the presence of modest differential attrition, we perform the following robustness checks:

- A differences-in-differences analysis in which we compare changes since baseline across the treatment and control groups.
- Bounding analysis to assess differential attrition

- Run the ‘midline and endline only’ specifications, but subset to cases where the outcome is non-missing at both midline and endline.

For any items marked as susceptible to outliers in the topic-specific component of the pre-analysis plan below, we will perform the following robustness checks:

- Estimate effects using median regression.
- Estimate a version of the estimates where we winzorize the outcomes at the 99th percentile.

5.7 False Discovery Rate Adjustment

Following Guess et al. (2023), the family-, component-, and item-level estimates will be placed into tiers for the purpose of multiple comparison adjustment. We use Benjamini and Hochberg (1995)’s false discovery rate adjustment to compute q-values; following Benjamini and Hochberg (1995) we do this within families of outcomes. We place our hypothesis tests into tiers (denoted K0, K1, K2, K3, and K4) as follows, corresponding with our prioritization of the tests:

- K0: Family-level estimates pooled across time. The q-values for these items will be computed using all the K0 items across families in a paper.
- K1: Component-level estimates pooled across time. The q-values for these items are computed using the K0 and K1 items in the outcome’s same family.
- K2: Primary item-level estimates pooled across time. The q-values for these items are computed using the K0, K1, and K2 items in the outcome’s same family.
- K3: All other estimates (“exploratory” tier). This includes family-level, component-level, and item-level estimates which are computed within each time period, estimates on items pre-specified as secondary or tertiary, and all tests of heterogenous treatment effects, as well

as descriptive analyses. The q-values for these items are computed using the K0, K1, K2, and K3 items in the outcome's same family.

- K4: Any post hoc comparisons conducted after filing these pre-analysis plans (e.g., in response to referee comments). The q-values for these items are computed using the K0, K1, K2, K3, and K4 items in the outcome's same family.

For example, when estimating the FDR-adjusted q-values for the primary item-level estimates (tier K2), we include the p-values for the treatment effects on every primary item in the entire paper (regardless of which family and component it is in or whether it is based on midline/endline surveys only or not), as well as the p-values from all the components and families.

In some cases, the plan for a family may deviate from this. For example, in some families, only one item is pre-specified to be included in the index for a given component, or only one component for the family. In such cases, the FDR adjustments will be done on one fewer "level" (e.g., if only one item is in a component, it will not be adjusted with K2, as it would already be adjusted at the K1 level for the component. If only one component is in a family, that component will be counted as K0, primary items counted as K1, secondary items as K2, etc.). For some families, there will also be a distinction between the secondary and tertiary items. In these cases, secondary items that are pooled across midline/endline and monthly surveys and secondary items that are pooled across midline/endline surveys only will be prioritized above other K3 and K4 items; this effectively pushes other K3 items to K4 and K4 items to K5. These cases will be flagged in the text.

Table 3 summarizes all of our estimates and the FDR tiers we place them in.

We will treat ordinal outcomes as continuous by default.

Table 3: FDR Tiers

	Pooled line/Endline Surveys	Across and Monthly	Mid- line/Endline Only (Omitting Monthly Surveys)	Pooled line/Endline Only (Omitting Monthly Surveys)	Across Surveys Monthly	Mid- line/Endline Only (Omitting Monthly Surveys)	Estimates At Each Time Period (e.g., at midline, in year 2, etc.)
Family	K0			K0			K3
Primary Components	K1			K1			K3
Primary Items	K2			K2			K3
Secondary Items	K3			K3			K3
Tertiary Items	K3			K3			K3
Heterogeneous treat- ment effects	K3			K3			Not calculated
Any post-PAP tests	K4			K4			K4

5.8 Attrition

We will present a set of results correcting for differential attrition. We will check for balance in attrition rates using the same set of covariates that we used to test for balance at randomization.

We will conduct two-stage sampling for midline and endline data collection to minimize attrition-related bias by concentrating resources and efforts on a randomly chosen subset of the cases that are the most difficult to reach (and adding weights accordingly). We will also keep track of the number of contacts required to reach each participant for each survey. We will consider using the randomly assigned intensive follow-up and number of contacts required to reach each participant to construct attrition adjusted treatment effect estimates.

5.9 Characterizing “Treatment” of Control Group Participants

Not all eligible respondents who complete the online eligibility screener will be randomly selected to participate in the program and study. As a result, we have access to an additional “control” group of individuals who consented to passively provide administrative data but will not be contacted by the research team. Using this “administrative control” group can help us shed light as to whether

the program has any effects on the “program control” group, either as a result of the \$50 monthly payments, the survey incentives, or the act of completing surveys themselves. We will use this group to characterize any such effects on outcomes measured using administrative data that might be present in the program control group.

These hypothesis tests are not the main focus of the paper so they are not subject to a multiple comparisons adjustment.

5.10 Elicitation of Forecasts

We will be eliciting forecasts for several key outcomes on the Social Science Prediction Platform. We expect to receive forecasts from other researchers, those working in policy or non-profit organizations, and the general public. These forecasts can help in gauging the novelty of our results (DellaVigna, Pope and Vivaldi 2019). There are not currently standard ways of presenting comparisons of *ex ante* forecasts with research results, but we anticipate including some comparisons, if only in an appendix. In comparing our research results to the *ex ante* forecasts, we will focus on comparing our results to the predictions of researchers in economics unless otherwise specified. The outcomes that we will forecast are indicated with an asterisk in the section on outcomes below.

5.11 Partial Pooling Analysis

There are some outcomes which may be relatively low-powered. For example, relatively few individuals may have direct engagement with the criminal justice system. To improve power, we will use a Bayesian hierarchical model to partially pool results across this study and several other programs we are evaluating, namely, the Chicago Resilient Communities Pilot program and the Cook County Promise Pilot program. This analysis will also help us understand and characterize potential heterogeneity in treatment effects.

The logic underlying Bayesian hierarchical models is that each study may be partially infor-

mative as to what another study will find, and so partial pooling may improve estimates. For our analyses, rather than use summary measures like treatment coefficients and standard errors, we will use individual-level data where possible in order to take advantage of covariates that vary at the individual level.¹⁸ For continuous outcomes, the default model and priors will be as the main model in Meager (2019); for binary outcomes, we will use a logistic regression model.¹⁹ We will also examine the sensitivity of the results to alternative priors.

The main outcomes considered in this analysis will be the items that are collected in all studies and denoted with an asterisk, for which we are collecting *ex ante* priors. Due to the potential for differential attrition in survey-based measures, the outcomes available in administrative data will be prioritized. In one set of robustness checks we will use these expert forecasts to inform the priors used in the mixed model.

We expect the partial pooling approach to be implemented in a separate paper following the conclusion of all the programs, although depending on the arrival of administrative data relative to the program end dates, it is possible that the analysis will begin with only two of the three programs' data.

6 Sustained Unconditional Cash Transfers and Intrahousehold Outcomes

Intrahousehold outcomes are important to gather for two reasons.

First, there could be spillovers within the household such that if we did not capture intrahousehold outcomes we would miss a large part of the effect of the transfers. For example, we may worry that with only one household member receiving a transfer, they may feel pressure from

¹⁸For some administrative data, it may not be possible to pool individual-level data across sites, in which case we will revert to pooling treatment coefficients and standard errors.

¹⁹In the case of rare events, we will compare our individual-level logistic model results with what one would obtain from a model based on the study-level log odds ratio point estimates and standard errors should we observe events affecting <1% of the study sample.

other household members to share the transfer. If we did not consider how these transfers could affect the entire household, we could mistakenly infer that the transfers had less of an effect than they did. It will be important for us to capture gifts given and received, but we may also expect other types of spillover effects. The composition of the household might change, as the recipient moves, separates or finds a new partner, or no longer needs to live with as many housemates to pay rent. The other members of the household may also feel more economically secure as a result of the transfers. If the recipient has a partner, they may feel more comfortable returning to school, spend more time taking care of any children, or be able to overcome barriers to employment such as not having reliable access to transportation. Since the transfers could benefit more people than the immediate recipient, we must do our best to capture this, and we expect the largest share of spillovers to occur within the household.

Second, the transfers could change dynamics within the household. For example, the person who receives the transfers may gain more decision-making power in the household due to their increased economic power. There is also a literature that suggests that lack of financial resources can contribute to domestic violence, both by increasing stress within the household and by making it harder for people in abusive relationships to leave (Schneider, Harknett and McLanahan 2016). We might therefore expect a reduction in domestic violence as a result of the transfers.

Due to both the possibility of spillover effects and the possibility of the transfers changing intrahousehold dynamics, we consider intrahousehold outcomes to be very important. The following section will discuss the outcomes we will consider in more detail.

7 Intrahousehold Outcomes: Survey Measures

This section describes the survey measures that will be used in each of seven families of outcome variables. Other potential data sources such as administrative records will also be highlighted where relevant. If there are substantial lags in obtaining any of these data, items relying on them

may be broken into a subsequent paper.

As noted, apart from considering the measures in each family separately, we will report a single index for each family (following, e.g., Finkelstein et al. 2012). On occasion, an outcome measure will be pre-specified to be excluded from this index as it may be useful descriptively but not make sense to include in an index. Measures of particular interest will be flagged in the following subsections.

All variables will be converted to unconditional variables wherever possible,²⁰ with exceptions flagged in the text.

Finally, given that individuals report some items in dollar amounts, which can be extremely large, some variables will be winsorized at the 99% level. As a general rule, any item reported in surveys in dollars should be expected to be winsorized at this level, unless otherwise stated, at the lowest possible level of aggregation. For a robustness check, we will perform median regression using the unadjusted values.

7.1 Family 1: Household Stability

Sustained unconditional cash transfers could affect household composition. Some of the measures in this section will be purely descriptive, while others will be combined in a household stability index.

1. Number of household members, divided into several overlapping categories: a) adults (B25); b) children (B26, B27); c) related household members, including spouse/partner, child, mother/father, sister/brother, grandchild, and biologically related “other” (C3, C8, C13); d) non-related household members, including friends, boyfriend/girlfriend, foster children, and partner’s children (C3, C8, C13). These measures will not be included in the index but will still be presented.

²⁰For example, if someone doesn’t have a partner, questions about how many hours their partner spends on various activities will all take the value 0.

2. Presence of partner: a) whether the respondent lives with a romantic partner (so_3, C3, intratd_1). This measure will not be included in the index but will still be presented.
3. Presence of parents: a) whether the respondent lives with a parent (C3). This measure will not be included in the index but will still be presented.
4. Change in household composition: a) number of times a romantic partner joined or left the household (primary measure: changes in C3. As a robustness check, we will also count changes through reconstructing a relationship timeline from relstat_2, so_3 and intratd_1, as well as moveout_intro_1, movein_intro_1, moveout_2, movein_4, movein_5); b) the total number of adults joining or leaving the household since baseline (C3, C8, C13, housecomp_1_1, housecomp_1_2, moveout_intro_1, movein_intro_1, moveout_2, movein_4, movein_5). To avoid double-counting partners in the index, this item for the index will exclude romantic partners and cover other adults, but we will also descriptively provide an estimate for all adults combining items a) and b); c) the total number of children joining or leaving the household since baseline (C3, C8, C13, moveout_intro_1, movein_intro_1, moveout_2, movein_4, movein_5). We will also descriptively consider the reasons for individuals moving in or out of the household (movein_2 and moveout_3). We will present a set of results considering only the SRC survey measures, but as changes in household composition may be frequent we will also use all responses in an alternative specification. Children who age into adults over the course of the study will not be considered as having “left” or “joined” the household.

Note: For all items in this pre-analysis plan, “total number of times” questions will only be readily interpretable if we have high (>90%) response rates. If we do not have such high response rates on mobile surveys, we will create average values of responses over the pre/post midline period instead.

7.2 Family 2: Spillovers to Household Members

This family will consider spillover effects on others in the household. Combining these disparate spillovers into a single index makes relatively little sense, so each will be considered separately. Each component in this family has some primary and secondary measures; the top-level FDR corrections within this family will be applied across the components in the family as constructed from the primary measures. Additional FDR corrections will be applied across the primary and secondary items.

1. Transfers to/from friends and family: a) whether participants provide any monetary assistance (Y2); b) whether they receive any monetary assistance (negative) (Y5); c) how many people they provide assistance to (Y3, coded as 0 if no help is provided); d) how many people they receive assistance from (negative) (Y6, coded as 0 if no help is received); e) the value of transfers given (finhelp_3, Y4); f) the value of transfers received (finhelp_6, Y7). We will pay particular attention to (*) the net value of transfers to friends and family, constructed from the value of transfers given (finhelp_3, Y4) and value of transfers received (finhelp_6, Y7). This is the primary measure for this component. We will subtract finhelp_6 from finhelp_3 and Y7 from Y4, respectively, and report this measure separately as it is key to understanding the impact of the program's cash transfers. In particular, if respondents give away some of their cash transfers, this will affect their other outcomes. Similarly, if they receive fewer transfers from others as a result of the program, it will tend to lessen the effect of the program. finhelp_3 and finhelp_6 are asked by mobile surveys every 6 months, immediately after running through a list of categories in which help could have been given or received, while Y4 and Y7 are asked in the SRC surveys. We will also present descriptive breakdowns of the categories in which help was given or received and the average percent reporting giving or receiving that type of help (help_1_1 through help_2_10). Since there is likely to be great heterogeneity in receipt of these transfers, we will also present exploratory

summary statistics including the 10th, 25th, 50th, 75th and 90th quantiles of the net value of help given and received. Those providing or receiving no help will be coded as \$0 for that measure. Items with a dollar value may be sensitive to outliers, so we will winsorize at the 99% level by default and perform median regression on the unadjusted values for a robustness check.

2. (*) Income spillovers: this value will be calculated as the difference between household income and the study participant's individual income on tax returns for couples filing jointly. If we are unable to observe this value for at least 30% of those in our sample who are living with a partner, we will use the difference between the respondent-reported total household income (M24) and the individual's self-reported total income (M6). As an alternative, exploratory measure, we will consider the total amount of extra income the respondent reports any other household member as having earned (incomchg_9 through incomchg_11) minus the total amount of income the respondent reports any other household members as having lost (incomchg_22 through incomchg_24).²¹ We will also consider changes in income that are due to gifts or government policy (incomchg_12_7 plus incomchg_12_9 minus incomchg_25_8), but this will be exploratory. As before, items with a dollar value will be considered sensitive to outliers and winsorized at 99%, with a robustness check performing median regression on the unadjusted values.

3. Employment spillovers: We are collecting a number of outcome measures regarding other household members' employment. Some are unambiguously good or bad and will be combined in a household index. However, as an exception to our normal procedure, we will also create a variable simply indicating participant partners' labor force participation and hours worked (using intratd_4, C3, D5 and intratd_4, C3, D7, D9, respectively, the latter weighted

²¹The question numbers for the income change questions changed; this pre-analysis plan will refer to the original question names throughout, but it should be remembered that the incomchg* questions have a incomchg1mo* version of them, and the pre-analysis plan is implicitly referring to the latter, where the former can be crudely converted to the latter by dividing by 3 to put it on the same 1-month timescale.

by number of months worked, as in the “partner’s employment status” component under the relationship characteristics family, as well as administrative data where available). We will use this to estimate partners’ labor supply elasticities. Despite the potential for selection, these outcomes will be of primary importance, and they will be analyzed comparably to the labor supply elasticity family in the employment pre-analysis plan. Selection will be explored as described under the relationship characteristics family. The items for the household index are: a) total number of times someone else in the household was promoted (newjob_h_2 plus newjob_h_5); b) quality of any new job of someone else in the household (combining trigger module Likert scale questions comparing the new job to the old job in an additive index (newjob_h_4* plus newjob_h_7*), then averaging across new jobs); c) total number of times someone else in the household was laid off or left because of illness or injury (negative) (leftjob_h_3_1 or leftjob_h_3_10 plus leftjob_h_6_1 or leftjob_h_6_10); d) total number of times someone else in the household left a job because they found a job they enjoyed more (leftjob_h_3_3 plus leftjob_h_6_3), found a job that was a better fit with their skills and experience (leftjob_h_3_4 plus leftjob_h_6_4), found a higher-paying job (leftjob_h_3_5 plus leftjob_h_6_5), or enrolled in school or training (leftjob_h_3_7 plus leftjob_h_6_7); e) total number of times someone else in the household received a raise (incomchg_12_1); f) total number of times someone else in the household received more income from working more hours, received a bonus or commissions, or had additional or more consistent contract or gig work (incomchg_12_2 through incomchg_12_4); g) total number of times someone else in the household received more income from a new part- or full-time job (incomchg_12_5 through incomchg_12_6); h) total number of times someone else in the household received a pay cut (negative) (incomchg_25_1); i) total number of times someone else in the household worked fewer hours through losing a full-time or part-time job (negative) (incomchg_25_2 through incomchg_25_3); j) total number of times someone else in the household worked fewer hours involuntarily or through illness or injury (negative)

(*incomchg_25_5* through *incomchg_25_6*). We will also report the total number of people who left their job because they did not like it (*leftjob_h_3_6* plus *leftjob_h_6_6*) or left due to family responsibilities (*leftjob_h_3_9* plus *leftjob_h_6_9*), but these will not be included in the index due to it being ambiguous whether they represent something positive or negative (for example, leaving a job one doesn't like can be positive, but their not liking the job that they had, which they could have obtained during the study, could indicate a failure in bargaining for better terms, etc.). We will separately report items that have an ambiguous interpretation: the total number of times someone else in the household found a new job or changed jobs (*jobintro_1_2_1*, or *newjob_h_1_1* for the partner or *newjob_h_1_3* for another household member, respectively), the total number of times another household member left a job (*jobintro_1_1_1*, or *leftjob_h_1_1* for the partner or *leftjob_h_1_2* for another household member, respectively), the total number of times another household member decided to stop working (*incomchg_6_7*), or their income decreased because they worked fewer hours voluntarily (*incomchg_25_4*). We will also consider, as an exploratory measure, the average response to how likely it is that someone else in the household who left a job will find a new one in 6 months (*leftjob_h_4* plus *leftjob_h_7*, reverse coded). We will separately consider spillovers to one's partner vs. spillovers to others in the household, and only spillovers to one's partner will be included in constructing the primary component; spillovers to others in the household will be considered exploratory. We cannot distinguish between partners and others in the household for items (e)-(j), so they will be considered secondary items. It should be noted that all "total number of times" questions will only be readily interpretable if we have high (>90%) response rates, else we will have to calculate likelihoods (average values across time) rather than total number of times, as described earlier. At the time of updating this pre-analysis plan, the plan is to use average values throughout. Outcomes will be considered unconditionally here (e.g., if the participant lives alone or without a partner for the outcomes specific to partners, that variable takes the value 0).

4. Education spillovers: a) whether someone else in the household began schooling or job training (school_1_1); b) if someone else in the household began schooling or job training, was it part- or full-time (school_6, full-time = 2, part-time = 1, did not begin school or training = 0); c) if someone else in the household began schooling or job training, was it a formal program (school_7, 1 if items 1 through 5, else 0).

5. Expenditure spillovers: a) total cost of major expenditures when someone else in the household incurred an unexpected cost, as reported in the trigger modules (unexp_4 if unexp_1_1 = 2, 0 otherwise). Given that this measure (unexp_4) could combine other household members' expenses with the respondent's expenses, care must be taken in interpretation. We will restrict attention to those cases in which the respondent does not have their own unexpected expenditures, i.e. unexp_1_2 does not take the value 1. Further, since these measures report only unexpected expenditures, some of which could be exogenous, this measure will be descriptive and excluded from the index. We will also descriptively note the percent of the time that when someone else in the household received extra income, the household spent at least some money on items in each of the main categories in the consumption module (i.e., housing, durable goods, non-durable goods and services, human capital investments, and net transfers to/from other individuals from incomchg_15*). The analysis of these data is complicated by the fact that respondents are potentially reporting uses of money from many sources combined (i.e. own changes in income plus household changes in income), so again, these measures remain descriptive, though we will contrast spending in these categories when an individual says they themselves received extra income to spending in these categories when an individual says someone else in the household received the extra income.

6. Financial health spillovers: a) whether, if someone else in the household incurred a major expenditure, they were able to pay for it using savings or money they had on hand (unexp_5_1 through unexp_5_2, unexp_1_1; takes the value 1 if there was either no major expenditure

incurred by someone else in the household or there was a major expenditure but it could be paid for in this way, 0 otherwise); b) whether, if someone else in the household received additional income, money was saved, invested, or used to pay down a debt (incomchg_14_1 through incomchg_14_3; takes the value 1 if someone else in the household received additional income and it was used in this way, 0 otherwise); c) credit scores of others in the household from Experian data; d) trades per inquiry (approval rate) of others in the household; e) credit limit on all revolving accounts of others in the household; f) utilization of credit (percent of revolving credit used) of others in the household. Items c) through f) will use data from Experian. Since some people will not have enough credit history to generate a credit score, we will descriptively consider both the credit score itself and whether the treatment changed the number of other people in the household that have a credit score. For those without revolving accounts, item e) will take the value 0; even people without revolving accounts or a credit score might have previously applied for credit, but items d) and f) will be removed from the index and considered descriptively if at least 5% of households have no household member other than the participant who made inquiries in the data. Finally, item b) is descriptive due to the many potential sources of the extra income, as in the previous outcome. It should be noted that the way that Experian provides the data, we may only receive data about other adults in the household without knowing who they are or their relationship to the participant, so these measures are somewhat speculative.

7. Healthcare spillovers: a) total cost of major expenditures incurred for healthcare when someone else in the household incurred an unexpected cost (unexp_2_3 plus unexp_2_4 if unexp_1_1 = 2, 0 otherwise); b) whether someone in the household had to forgo care because of cost (V20); c) whether a child had to forgo care because of cost or not being able to take time off work (V30). Again, caution must be taken in interpreting a), so that item will be descriptive and not included in the index.

8. Crime spillovers - victimization: a) the average value of whether someone else in the household was the victim of a crime (crimevic_3). Descriptively: what type of crime (crimevic_4*)?

Since changes in household composition could also affect these measures, in a robustness check we will construct this family of measures separately for two groups: households whose adult members changed since baseline and households whose adult members did not change since baseline. We will also include household size as a control variable and implement the Heckman correction procedure to account for selection in a further robustness check.

7.3 Family 3: Relationship Status

This section will consider the impact of cash transfers on respondents' relationship status and relationship stability. These outcomes do not condition on relationship status (i.e. we can assign a value to each item even for participants not in a relationship) so will be combined in the index.

We emphasize that being in a relationship or being in a relationship for a long time should not necessarily be taken as positive: it could, for example, be negative if the relationship is of poor quality. Hence, this family of outcomes can only be interpreted with reference to the family of outcomes on relationship characteristics and domestic violence.

1. Relationship status: a) whether the respondent is in a romantic relationship (so_1, relstat_1_1 and relstat_1_2, C3, intratd_1; note that C3 and intratd_1 ask about romantic partners in the household and therefore may not be comprehensive. relstat_1_1 and relstat_1_2 may be hard to interpret as they ask about beginnings/ends in the last 6 months, so we will always prefer the other variables when they are available) (*); b) whether this person is a spouse/partner or a girlfriend/boyfriend (1: C3=spouse/partner; 0: C3=girlfriend/boyfriend or none); c) whether the respondent is separated or divorced (negative) (B22).
2. Relationship stability: a) how long the respondent has been in the relationship (so_2) or 0 if not in a relationship; b) number of times the respondent started or ended a relationship in

the last year (negative) (estimated from relstat_1_1, relstat_1_2, which ask about the last 6 months). We will also consider, descriptively, reasons for relationships ending (relstat_4*) and whose choice it was (with the dependent variable being dummies for “mutual”, “mostly you”, or “mostly partner”).

7.4 Family 4: Relationship Characteristics

Relationship quality and partner attributes may also change over the course of the study. To investigate this, we will consider the following outcomes:

1. Relationship quality: a) relationship with partner is happy (Likert) (so_7, relstat_3); respondent is not sure they can trust their partner (negative) (so_5).
2. Partner’s employment status: a) whether the partner works (intratd_4, C3, D5) (*); b) the number of hours the partner works (intratd_4, C3, D7, D9, the latter weighted by number of months worked); c) whether the partner is a regular, permanent employee (D6: coding 5 as 1 and 1, 2, 3 and 4 as 0; C3); d) number of months partner worked in the last 12 months (D8, C3). We will also consider whether the partner worked using tax return data for those filing jointly, however, we expect this may be underpowered. For increased power, we will consider the survey-based measures for those partners that are not reported on joint returns.
3. Partner’s relationship history: a) whether the respondent is in a relationship (C3) with someone who is separated or divorced (D10); b) whether the respondent is in a relationship (C3) with someone who has children outside the household (D11 > count of children in C3. This would only capture some cases of a partner having children, but nonetheless may be meaningful. Whether the partner has children at all (D11) can be considered alone in a robustness check, though the interpretation would be different).
4. Partner’s education: a) partner’s highest level of education (C3, D4); b) whether partner is in

school or a training program (C3, D3).

The items in this family may change due to selection, and indeed these changes would be of particular interest. While some of the changes in partner attributes may be due to changes in the same partners (e.g., a partner may obtain more education over the course of the study), we anticipate that the changes in this family of outcomes will primarily reflect changes in partners. To determine whether the observed changes are due to such selection, we will: a) present results separately for those who stayed in the same relationship over the course of the study and those who did not; b) model the selection using a Heckman correction.

For the primary analyses in this family we will focus on those considered partners/spouses (C3), though in a secondary analysis we will consider any romantic relationship (also including girlfriends/boyfriends).

7.5 Family 5: Intrahousehold Division of Labor

We are unlikely to be able to survey household members other than the individual enrolled in the study. Therefore, to gauge intrahousehold division of labor, we will focus on asking the individual enrolled in the study some basic questions about their partner's time use, if they have a partner. We acknowledge that these responses may be quite noisy and thus any estimates of changes in intrahousehold division of labor may be biased towards zero. Further, by restricting attention to how participants' partners spend their time, we may miss changes in how other household members spend their time. However, given the diversity of possible household arrangements, we choose to focus on spillovers to partners and division of labor with partners as we expect that households with a partner will constitute a relatively large share of households, and we expect that respondents may be more likely to know how their partner spends their time than how other people in the household spend their time. This family will focus on those with partners; the unconditional effects on a participant's time use are separately considered in the time use pre-analysis plan. However, there

could be selection in that the transfers may affect participants' relationship status and partners. We will account for this using a Heckman correction in a robustness check.

In particular, we will ask respondents to estimate how many hours per week their partner engages in each of several activities, adapted from Aguiar, Hurst and Karabarbounis (2013): hours spent caring for others (including child care + elder care) (inratd_3), hours spent working (inratd_4), hours in home production (inratd_5), and hours of leisure (inratd_6). We expect these measures may at times be overstated, so the main regressions will winsorize at the 99% level. As a robustness check, we will perform median regression on the unadjusted sample.²² We will compare the respondent's answers for their partner with their responses for themselves to determine what share of the total hours spent in each of these categories was spent by the respondent as opposed to their partner. However, these percents may mask changes in the absolute number of hours spent on each type of activity. For example, it is possible that both partners increase work hours or increase hours spent on leisure activities as a result of the transfers; this would be important to know even if the share of hours spent by each partner changes. Therefore, we will first report the absolute number of hours reported spent in each activity and prioritize that measure.

Given the possible noise in these measures, we will also ask respondents two simple questions: a) who is the primary breadwinner in the household? (inratd_8) (*), and b) who is the primary caregiver in the household? (inratd_9) (*). For each question, they may choose "myself", "my partner", "both myself and my partner about equally", or "someone else"; for analysis, these will be recoded with inratd_8 and inratd_9 taking the value of 2 for "myself", 1 for "both myself and my partner about equally" or "someone else", and 0 for "my partner".

We will present results for each of the aforementioned categories (hours spent working, hours spent caring for others, hours in home production, hours of leisure) as well as the two questions about who is the primary breadwinner and caregiver. After presenting the aggregate results for

²²As part of ordinary data cleaning, we bound the number of hours per week that someone can spend on an activity at 168 hours.

these measures, we will also break down responses by the sex of the study participant and by whether or not they have children.²³ The preferred specification will focus on those who are living with a partner. The primary outcome measures will be the questions on who is the primary breadwinner and who is the primary caregiver; in combining these into the index, being the primary caregiver will be coded as negative because it may be expected to be negatively correlated with being the primary breadwinner, but this is not a judgment on the value of either activity. For each of these measures, we will run regressions on an indicator variable of having selected “myself” as a response. As a secondary outcome, we will consider the indicator variable of having selected “my partner”.

For the FDR adjustments, we will make one adjustment at this level (two items); one for these items plus the dummies in which the participant selected “my partner” and the aggregate of other categories (hours spent working, hours spent caring for others, hours in home production, hours of leisure, for each of self and partner); one for all the aforementioned items plus heterogeneity tests by sex and whether they have children, as well as the specifications involving percents.

All variables will be converted to unconditional variables wherever possible. For example, if someone doesn’t have a partner, they will be the primary breadwinner and caregiver, and the questions about how many hours their partner spends on various activities will all take the value 0.

7.6 Family 6: Decision-Making Within the Household

For those households in which the respondent has a partner, we will construct an index of decision-making power within the household by asking who among them has a greater say in making each of the following types of decisions (intrad_7*). The options for answering each question are: “myself”, “my partner”, “both equally”. We will treat “both equally” as taking a value between “myself” and “my partner” (i.e. myself = 2, both equally = 1, my partner = 0). If a person doesn’t

²³Unless otherwise noted, those self-identifying as “other” at baseline will be pooled with those self-identifying as “female” for analyses.

have a partner, “myself” will be assumed for all options. Given that there may be self-reporting bias, we will focus on changes from baseline rather than absolute amounts.

1. Expenditures: a) large household purchases, b) small household purchases for daily needs, c) borrowing.
2. Housing: a) where to live.
3. Health: a) determining your healthcare.
4. Social: a) visiting family and friends.
5. Children (conditional on having any): a) purchases for children, b) children’s education.

Two of these questions only pertain to households with children. These questions will not form part of the main index, but we will conduct a secondary analysis focusing on households with children in which these questions would be included.

In addition, one Likert question on whether the respondent and their partner are a team when it comes to making decisions will be asked but not included in the index (so_6); this will be recoded to the maximum value in the case the individual does not have a partner.

7.7 Family 7: Domestic Violence

We will use the HITS domestic violence screening tool. (*) Respondents will be asked (hits_1*) how often their partner has exhibited each of the following behaviors (“never”, “rarely”, “sometimes”, “fairly often”, or “frequently”):

1. Physically hurt you
2. Insult or talk down to you
3. Threaten you with harm

4. Scream or curse at you

The convention for this index is to classify someone as suffering from domestic violence if their aggregate score is 10.5 or higher, where 1 = never and 5 = frequently (Sherin et al. (1998)). To use a slightly broader definition (since a high score on any single measure could arguably be considered domestic violence) we will consider someone to be suffering from domestic violence if exceed any of the following cut scores from Shakil et al. (2014): 1.5 for “physically hurt you”; 2.5 for “insult you or talk down to you”; 1.5 for “threaten you with harm”; 3.5 for “scream or curse at you”. We will use the 10.5-point cutoff threshold for classifying someone as suffering from domestic violence in an alternative specification, and we will also report the total raw scores. In the forecasting exercise, we will ask individuals to forecast the total raw scores.

This family of outcomes is only asked of those in relationships; for an unconditional analysis of outcomes we will assign those not reporting a relationship a score of 0. However, the potential for selection is inherently interesting, so to further investigate the causes of any changes we will separately report scores for those who stayed in the relationship they had at baseline (exploratory)²⁴ as well as modeling selection using a Heckman correction.

While intimate partner violence can affect those of any sex or gender, we will also restrict attention to those who identify as female in an exploratory analysis.

In a further exploratory analysis, we will also separately restrict attention to those deemed to be suffering from domestic violence at baseline and investigate whether a greater share of those in the treatment group left the abusive relationship or no longer live with the abusive partner.

²⁴This will be restricted to those who were living with the same person since baseline, since we only ask for identifying information of people in the household.

8 Conclusion

8.1 Known Limitations

Our study has several limitations. First, the limited nature of the RCT does not permit us to simulate the macroeconomic conditions of the government introducing an unconditional cash transfer program to all residents of the United States who meet broad eligibility criteria. If recipients are spending the money helping friends and family who would receive their own cash transfer under the policy, the treatment is diluted and the likelihood of the hypothesized effects is undermined. Similarly, the dispersed sample precludes our ability to capture the multipliers and general equilibrium effects identified in the theoretical literature and observed in studies in developing countries. The dispersed study also precludes studying the effect of sustained unconditional cash transfers on cultural attitudes towards work and other social spillovers. Despite these limitations, we selected a geographically dispersed population for several reasons. Most importantly, the intervention is very expensive and our sample size is constrained by the budget. A geographically saturated study would likely cost billions of dollars, and we would not have enough statistical power to detect effects with a geographically saturated study with our budget.

A second limitation is the time-bound nature of our treatment. The 3-year timespan of the intervention is obviously not the same as a perceived long-term guarantee, and individuals may behave differently knowing that the transfers are time-limited (Hoynes and Rothstein 2019). Nevertheless, a study at the scale proposed in this analysis plan will allow us to provide timely evidence to inform ongoing policy debates and future research on this topic.
